ABSTRACT

Breast cancer is the neoplasm most diagnosed malignancy and the leading cause of mortality among women on a global scale. A profound increase in the understanding and clinical management of breast cancer has occurred over the past two decades, which has led to significant progress in prevention, early detection, and personalized breast cancer therapy. However, the biggest obstacle still faced in clinical practice is the complete understanding of intertumoral and intratumoral heterogeneity, in addition to the mechanisms of multiple drug resistance in the systemic treatment of the disease. In view of this, many studies focus on analyzing morphological and, mainly, molecular patterns of breast cancer, with the purpose of grouping these tumors into classes or entities to assist in clinical management, in the elaboration of epidemiological and functional studies, and in the performance of clinical trials. The most common special histological types of breast cancer include: medullary carcinoma, metaplastic carcinoma, apocrine carcinoma, mucinous carcinoma, cribiform carcinoma, tubular carcinoma, neuroendocrine carcinoma, classic lobular carcinoma, and pleomorphic lobular carcinoma, in addition to the non-specific type of invasive ductal carcinoma, which constitutes the majority of newly diagnosed cases. As to their molecular aspect, intrinsic subtypes were identified based on global studies of gene expression profiles. Today, four molecular subgroups are widely reproduced and well established in the clinical routine, namely: Luminal A, Luminal B, HER2+, and Triple Negative. Thus, the present article aims to briefly address the histological and molecular classification of breast cancer.

KEYWORDS: breast cancer; classification; neoplasms.

INTRODUCTION

Cancer has become one of the main causes of morbidity and mortality on a global scale in recent decades, as a result largely due to demographic, economic and epidemiological transitions. Among the female population, breast cancer is the most common malignancy in the world (154 out of 185 countries), except in West Africa, where cervical cancer prevailed. In 2018, a total of 2.1 million women were diagnosed with breast cancer, approximately one new case diagnosed every 18 seconds. In addition, breast cancer also represents the highest cancer mortality rates in women across the globe (103 out of 185 countries), with roughly 626,600 deaths due to the disease, with the main exceptions being the countries of Northern Europe, South America North and Sub-Saharan Africa, where the main causes of death were due to cervical and/or lung cancer.

In Brazil, according to the latest publication for the 2020–2021 biennium, produced by the National Cancer Institute (INCA), approximately 66,280 new cases of breast cancer annually, with an estimated risk of 61.61 cases per 100 thousand women. Without considering non-melanoma skin cancer, this type of malignancy is the second most incident in the general population and the most incident among the female population in Brazil, representing 29.7% of all cancer cases in this population, surpassing the world average, estimated at 24.2%. It is known by the scientific community that the morphological and molecular aspects of breast cancer have been thoroughly explored and that these studies sought further clarification of the tumor heterogeneity of breast cancer. Therefore, this article aims to briefly address the current status of the histological and molecular classification of breast cancer. For that to be accomplished, articles were searched in the PubMed database without language restrictions. The search terms “breast cancer” were used in combination with specific terms that cover the different histological and molecular subtypes, as appropriate. We selected publications widely over
the last five years, and did not exclude older, commonly referenced and highly regarded publications. We also searched the reference lists of articles identified by this search strategy and selected those that we deemed relevant.

**HISTOLOGICAL CLASSIFICATION**

For the morphological study of breast cancer, we must understand whether the tumor is limited to the epithelial component of the breast or has invaded the surrounding stroma, and whether this tumor appeared in the mammary ducts or lobes. However, in histopathological practice, cell type characteristics, number of cells, type and location of secretion, immunohistochemical profile and architectural characteristics determine if the tumor is ductal or lobular, in addition to its sub-classifications, rather than its precise location in the mammary tissue. About 50% to 80% of newly diagnosed breast cancer cases are classified as invasive ductal carcinoma (IDC); the rest of the cases are classified as invasive lobular carcinoma (ILC). IDCs can be classified as “no specific type” because these tumors do not present sufficient morphological characteristics to be determined as a characteristic histological type; they can also be recognized as a “special type” if they present sufficient distinctive characteristics, and particular cellular and molecular behavior. The most common special types of breast cancer include: medullary carcinoma, metaplastic carcinoma, apocrine carcinoma, mucinous carcinoma, cribriform carcinoma, tubular carcinoma, neuroendocrine carcinoma, classic lobular carcinoma, and pleomorphic lobular carcinoma.

**Invasive ductal carcinoma no specific type (IDC-NST)**

The histological subtype IDC-NST is the most common, constituting about 40% to 75% of all invasive breast carcinomas. Usually, it has a wide scope of morphological variation and clinical behavior. Tumor cells are pleomorphic, with protruding nucleoli and numerous mitoses. Areas of necrosis and calcifications can be detected in more than half of the cases.

**Medullary carcinoma**

Special subtype of invasive breast carcinoma, responsible for approximately 5% of all cases, and associated with better clinical results and lower rates of involvement in axillary lymph nodes. It usually affects patients between 30 and 40 years old and is often associated with mutations in the BRCA1 germline (Breast cancer gene 1). Microscopically, it is a well-circumscribed carcinoma, composed of large and pleomorphic tumor cells, with a syncytial growth pattern, frequent mitotic figures and prominent lymphoplasmacytic infiltrate. Other commonly seen features include spindle cell metaplasia and giant tumor cells.

**Metaplastic carcinoma**

This histological subtype is characterized by the dominant component of metaplastic differentiation, representing approximately 1% of all cases and affecting women, mainly in post-menopause. This group of tumors shows aggressive biological behavior and an often lymph node involvement. Morphologically, it is a poorly differentiated heterogeneous tumor that contains ductal carcinoma cells mixed with other histological elements, such as squamous cells, spindle cells or other mesenchymal differentiation, such as chondroid cells, bone cells, and myoepithelial cells.

**Apocrine carcinoma**

It constitutes about 1% to 4% of all cases, with prominent apocrine differentiation comprising at least 90% of tumor cells. This subtype is generally of high histological grade, with poor prognosis and affects a wide age group, but it is more commonly seen in postmenopausal women. Microscopically, tumor cells are large, with an abundant granular eosinophilic cytoplasm, positive for PAS (Periodic acid-reactive Schiff) staining and prominent nucleoli; in addition, bizarre tumor cells with multilobulated nuclei can also be observed.

**Mucinous carcinoma**

It is a special subtype of breast cancer, also known as colloid, gelatinous, mucous and mucoid carcinoma, responsible for 2% of all newly diagnosed cases. This subtype has been associated with a favorable prognosis and often affects women over 60 years of age. Morphologically, these tumors have abundant amounts of extracellular mucin, surrounding small clusters of tumor cells with different growth patterns and with mild nuclear atypia.

**Cribriform carcinoma**

Special subtype associated to a good prognosis, generally affecting patients who are approximately 50 years old and constituting about 1% to 3.5% of all breast cancer cases. Cribriform carcinoma has almost no evidence of regional or distant metastasis. Microscopically, this subtype presents islands of uniform tumor cells, with low-grade atypia, cribriform appearance in 90% of the tumor and often associated with DCIS (Ductal carcinoma in situ) without well-defined stromal invasion.

**Tubular carcinoma**

Well-differentiated subtype, occurring in women between 50 and 60 years of age and constituting about 20% of all newly diagnosed cases. Most tubular carcinomas are associated to a wide range of potentially premalignant proliferative lesions. This subtype is characterized by the proliferation of prominent tubules (> 90%), which can be angled, oval or elongated, with a
disorganized disposition and open lumen covered by a single layer of epithelium, usually without presentation of necrosis and mitosis (Figure 1F)\(^22\).

**Neuroendocrine carcinoma**

It constitutes about 0.5% to 5% of all cases of breast cancer and commonly occurs in older ages\(^10\). This type of tumor has characteristics similar to neuroendocrine tumors of the gastrointestinal tract and lung, consistently expressing the markers chromogranin A and synaptophysin in more than 50% of neoplastic cells\(^23\). Morphologically, there is an infiltrative growth pattern with solid aggregates of tumor cells arranged in alveolar, trabecular or rosette patterns, and peripheral palisades can also be observed\(^12\). Neoplastic cells can be of different sizes and generally have fine eosinophilic granular cytoplasm (Figure 1G)\(^24\).

**Invasive lobular carcinoma**

It is the second largest biologically distinct carcinoma, representing about 5% to 15% of all newly diagnosed cases and generally affecting women of advanced age\(^11\). The classic form of the ILC is characterized by the presence of small tumor cells with little atypia, uniformly distributed throughout the stroma in a concentric pattern (Figure 1H)\(^10\). Among pleomorphic ILC, tumor cells have a hyperchromatic and eccentric nucleus, prominent mitoses and apocrine. Histiocytic or signet ring cells can be observed (Figure 1I) and they are more likely to have TP53 mutations (Tumor protein 53)\(^25\).

**MOLECULAR CLASSIFICATION**

We now know that breast cancer represents a biologically and phenotypically heterogeneous collection of diseases with different clinical and treatment response behaviors\(^26\). In this era of
modern medicine, only the morphological classification (nuclear grade, tubular grade, mitotic index, histological grade, and architectural characteristics) and the clinical pathological parameters (tumor size, lymph node involvement, metastasis), are insufficient to predict the real behavior of breast tumor pathophysiology\textsuperscript{10,27}. Thus, many studies focus on analyzing the molecular patterns of breast cancer in order to group these tumors into classes or entities to assist in clinical management, in the preparation of epidemiological and functional studies and in the performance of clinical trials\textsuperscript{28-34}.

The pioneering work by Perou, Sorlie and colleagues at the beginning of this millennium classified breast cancer molecularly into distinct subgroups, based on similarities in gene expression profiles, using the cDNA microarray technique\textsuperscript{31,33,34}. Thus, these studies demonstrated that there are breast cancer subtypes with differences in gene expression patterns, reflecting the individual phenotype, disease prognosis and systemic treatment planning\textsuperscript{35}.

Based on comprehensive gene expression profile studies, four clinically relevant molecular subtypes were revealed: Luminal A, Luminal B, enriched HER2 (HER2+), and Triple Negative (TN) (36). The groups of genes responsible mainly for the segregation of the molecular subtypes of breast cancer are genes related to the expression of estrogen receptors (ER), progesterone receptors (PR), HER2 (Human epidermal growth factor receptor 2), and cell proliferation regulator (Ki-67)\textsuperscript{1}. The Immunohistochemical (IHC) panel with these four biomarkers (ER/PR/HER2/Ki-67) has been considered efficient and significant in the stratification of these molecular entities\textsuperscript{6,35}. However, the growing need to improve risk stratification and accurate prognosis determination, in addition to an accurate understanding of tumor biology, led to the development of many multigenic assays, such as Oncotype DX, Prosigna PAM50 and Mammaprint\textsuperscript{36-39}. The signature of 70 genes (Mammaprint) and of 21 genes (Oncotype DX) are being used in patients with ER+ disease at an early clinical stage to distinguish women who may have the greatest risk of recurrence and who would benefit from adjuvant chemotherapy\textsuperscript{40,41}. The PAM50 trial (Prosigna) is a classifier for breast cancer subtypes. It also assesses a patient’s risk for distant recurrence of the disease and the likelihood of efficacy of neoadjuvant chemotherapy\textsuperscript{40,41}.

Molecular subtyping changed our view of breast cancer, with the possibility of stratifying this neoplasm in different entities that require specific treatments and different monitoring strategies, in addition to a better understanding of the pathophysiological pattern and clinical prognosis. Next, we briefly present the different molecular subtypes of breast cancer.

**Luminal A**

This molecular subtype is the most common and comprises approximately half of newly diagnosed breast cancer cases\textsuperscript{7}. According to the last update of St. Gallen in 2013, the immunohistochemical profile of this subtype was defined as: ER+ (≥ 1%), high expression of PR (≥ 20%), HER2- (≤ 10%), and low levels of Ki-67 (< 14%)\textsuperscript{42}. In addition, these tumors have characteristics of luminal epithelial cells of the breast, such as the high expression of cytokeratin’s 7/8/18/19\textsuperscript{43}. They include a wide range of low histological grade variants, such as IDC-NST, tubular, cribriform, mucinous, and classic ILC\textsuperscript{6,43}. This subtype has been associated with a highly favorable prognosis, with a more indolent clinical course, and generally shows less lymph node involvement\textsuperscript{44}. Nonetheless, due to the positive status of hormone receptors, patients benefit from endocrine therapies, either with selective estrogen receptor modulators (tamoxifen) or with aromatase inhibitors (anastrozole) (Table 1)\textsuperscript{45}.

**Luminal B**

Responsible for approximately 20% to 30% of invasive breast cancer cases\textsuperscript{26}. This subtype can be categorized immunophenotypically into Luminal B (HER-): ER+ (≥ 1%), PR- or < 20%, HER2- (≤ 10%) and high levels of Ki-67 (≥ 20%); or Luminal B (HER2+): ER+ (≥ 1%), HER2+ (> 10%) and any level of PR and

ER: estrogen receptor; PR: progesterone receptor; HER2: human epidermal growth factor receptor 2.
Ki-67≤10%. The expression of low molecular weight cytokeratin’s from luminal epithelial cells is a rule26. This molecular entity generally presents a moderate histological grade, including most of the IDC-NST and associated with an intermediate prognosis, with greater likelihood of locoregional recurrence when compared to Luminal A44,47. Luminal B subtype is understood as the most aggressive form of ER+ breast cancer cases and often does not show benefits for hormone therapy (Table 1)27 (EXCLUDED). Luminal B subtype is understood as the most aggressive form of hormone-dependent breast cancer cases, requiring additional treatments to hormonal therapy, such as chemotherapy (when HER2 +/-) or targeted target therapy (when HER2 +) (Table 1)27. The main difference in the molecular aspect between the two lumenous subgroups is the increased expression of genes related to cell proliferation, such as NSEPI (Nuclease sensitive element binding protein 1) and cyclin E1 (CCNE1), in addition to the activation of certain alternative pathways of growth factors, such as PI3K (Phosphatidylinositol 3-Kinase) and Src (Proto-oncogene sarcoma) in Luminal B breast tumors26.

HER2+

It represents 15% to 20% of newly diagnosed breast cancer cases48. This subtype is characterized by a high expression of HER2 (> 10%), negativity for ER (< 1%) and PR (< 20%), and high expression of Ki-67 (> 20%)42. In addition to the immunophenotypic characterization routinely used to assess the status of HER2 in breast cancer, the FISH (Fluorescence in situ hybridization) technique has also been employed to assess gene amplification49. According to the latest clinical practice guidelines provided by the American Society of Clinical Oncology (ASCO), if the IHC result shows complete staining of the cell membrane with strong marking, the diagnosis is positive for HER2; if staining of low to moderate intensity is observed, it will be necessary to use the FISH assay with an additional observer to confirm positivity, and, finally, in cases with negative marking the complete weak staining of the membrane, the diagnosis can be confirmed as negative for HER226. HER2 overexpression occurs almost exclusively in the ILC pleomorphic variant27. The amplification of the gene and the elevated expression of the HER2 protein has been related to tumors of greater histological grade, high proliferative index and propensities to metastasis, leading to short disease-free survival and worse prognosis50. However, these tumors may respond well to drugs that block HER2 activity, especially humanized monoclonal antibodies (Trastuzumab) and molecular receptor tyrosine kinase inhibitors (Lapatinib)51,55.

Triple negative

This class of tumors constitutes from 10% to 20% of all breast cancer cases26. This subtype is characterized by the lack of expression of the hormone receptors ER (< 1%) and PR (< 20%) and the oncoprotein HER2(≤ 10%); moreover, they are highly proliferative tumors, according to the Ki-67 index (> 30%)42. Most TN tumors manifest as the IDC-NST histological type. However, they also include variants of medullary, metaplastic and apocrine carcinomas28. These tumors are generally more prevalent in patients with BRCA1 mutations and young women, with a higher histological grade, risk of loco-regional recurrence, contralateral disease and systemic relapse52. Many gene expression profile studies have been carried out to better understand the heterogeneity of this particularly aggressive form of breast cancer. Thus, TN tumors can be further divided into seven other distinct entities, including two basal-like types (BL1 and BL2), with a basal pattern of gene expression, but showing differences in the immune response; one of the luminal androgen receptor type (LAB), which presents differential expression of genes involved in androgen metabolism; one of the immunomodulatory type (IM), which presents important changes in the expression of genes involved in immunological signaling pathways; one of the claudin-low types (CL), characterized by the low expression of cellular junction proteins (claudins 3, 4 and 7, in addition to E-cadherin); and two of the mesenchymal type, namely, mesenchymal itself (M) and mesenchymal stem-like (MSL), both with positive regulation of the signaling pathways involved in EMT (epithelial mesenchymal transition), but differing in the signaling of genes associated to stem cells and angiogenic factors58,59,60,61. Despite its simple definition, this subtype has been a challenge for the clinic, due to its morphological, molecular and clinical heterogeneity and the lack of targeted therapies54. Non-surgical treatment of the TN subtype has been limited to platinum-based chemotherapy and PARP (Poly ADP-ribose polymerase) inhibitors for patients with BRCA1 and 2 mutations26,55.

Although great advances have occurred in high-performance molecular techniques and bioinformatics during the last decades, which allowed refinement in the stratification of breast cancer, molecular tests are still evolving, arising important questions:

- How many subtypes of this malignant neoplasm are there?
- Which molecular classification system is more robust?
- Are the classifications able to illustrate intratumoral heterogeneity and clonal evolution?
- How should we interpret breast cancer subtypes?
- Is it possible for different classification schemes in clinical practice to exist?
CONCLUSION

Despite great advances in the stratification of breast cancer subtypes, the greatest obstacle currently found in clinical oncology is the complete understanding of intertumoral heterogeneity (illustrated by tumor size, regional lymph node status, distant metastases and differences in survival), especially the intratumoral heterogeneity (illustrated by histological and biomolecular variability, chromosomal, genomic, metabolic and epigenetic changes, in addition to cellular plasticity and the tumor microenvironment), which impacts the adversity of diagnosis and accurate prognosis, and weakening strategies in personalized medicine. In addition, resistance to multiple drugs (RMD) is considered the biggest obstacle in the systemic treatment of breast cancer, making the disease often uncontrollable and leading to high mortality rates. The mechanisms underlying drug resistance are still poorly understood. However, anti-apoptotic resistance, ATP-dependent drug efflux pumps, changes in drug targets, epigenetic changes, EMT and miRNAs make up important factors for failures in anti-cancer therapies. In this context, hundreds of other candidates for biomarkers have been investigated and studied for potential implications for diagnosis, prognosis, drug targets and predictor of therapeutic response, “justifying regular reviews”.
